Abstract

Gait recognition is a developing biometric technique capable of identifying individuals from a distance, with wide-ranging applications such as video surveillance. A primary challenge is the extraction of discriminative gait features from silhouettes that are robust to variations in apparel, carried objects, and camera viewpoints. To address these limitations, this study introduces GaitSTR — a novel framework that harnesses pyramid mapping for enhanced temporal and spatial feature extraction, integrated with a deep neural network comprising dense layers. Pyramid mapping decomposes gait sequences into multi-scale spatial features, enabling GaitSTR to capture fine-to-coarse motion patterns and improve recognition under varying conditions. The method focuses on extracting distinctive feature representations at different frame levels, effectively utilizing spatial and temporal variations within video sequences. The proposed model utilizes a memory-augmented recurrent neural network (RNN) enriched with temporal attention to capture sequential motion cues, while spatial features are extracted through a densely connected attention-guided network. By employing the pyramid-based hierarchical feature extraction, along with attention mechanisms in both spatial and temporal component, the network can prioritize the most significant video segments, improving its efficiency and learning capacity for processing intricate gait data. The results are evaluated on four widely used benchmark datasets: GREW, OU-ISIR, OU-MVLP, and CASIA-B—achieving 92.4% on GREW, 95.2% on OU-ISIR, and 0.96 mean accuracy on OU-MVLP, and 98.4% (normal) on CASIA-B, surpassing state-of-the-art methods. These results underscore the robustness of our approach under diverse conditions, establishing a new benchmark for performance in gait recognition.

Keywords: Deep Learning; Pyramid mapping; Spatial variation; Time-based modulation; Gait Recognition.

1. Introduction

Gait recognition has emerged as a prominent biometric technique for identifying individuals based on their unique walking patterns. Gait offers the distinct advantage of enabling identification from a distance without requiring active cooperation from the subject (Song *et al.*, 2024) (Sethi, Prakash and Bharti, 2022). This contrasts with traditional anatomical biometrics such as fingerprints, facial features, DNA, or iris patterns (Gadaleta and Rossi, 2018) (Choi *et*

al., 2019) (Ma, Wu and Wang, 2017) . These features have made gait recognition a prominent area of research for surveillance-related applications, such as, biometric criminal investigation, law enforcement civil security, and smart transportation systems (Balazia and Sojka, 2018) (Bastos and Tavares, 2025) (Yao *et al.*, 2022) . As a result, significant research attention has been devoted to gait recognition in recent years (Sepas-Moghaddam and Etemad, 2023). Recent advancements in technology have established gait analysis (Prajapati, Kaur and Sethi, 2021) (Cai *et al.*, 2023) as a reliable and non-invasive method for clinical evaluation, particularly in the diagnosis of health conditions, identification of individuals, and assessment of locomotor patterns (Panahi and Ghods, 2018) (Erdaş, Sümer and Kibaroglu, 2021). However, the accuracy of gait recognition is often challenged by external variations such as changes in attire, carried objects, and camera perspectives (Hou *et al.*, 2023) (S. Mandlik *et al.*, 2025) (Huo *et al.*, 2026). This underscores the necessity of improving model robustness under diverse and unconstrained conditions (Wei *et al.*, 2024). Earlier studies have introduced multiple strategies to mitigate the challenges posed by changes in viewpoint, clothing, and carried objects (Mitra and Acharya, 2007) (Xu *et al.*, 2021) (Gao *et al.*, 2022). These traditional approaches are typically categorized into two groups: those utilizing the Gait Energy Image (GEI) (Mogan, Lee and Lim, 2024) (Chen *et al.*, 2018) (Ben *et al.*, 2020) (Xiaxi Huang and Boulgouris, 2012) (Gupta and Chattopadhyay, 2021) and those that interpret gait as sequence-independent sets (Lin, Zhang and Yu, 2021) (Chao *et al.*, 2022). While GEI-based techniques have been widely used, they often fail to capture detailed spatiotemporal cues, which can adversely affect recognition accuracy. In contrast, methods that represent gait as sequence-independent sets—though they have yielded promising results in previous studies—have primarily demonstrated effectiveness within controlled laboratory environments.

To mitigate the aforementioned challenges —such as variations in clothing, carried items, and camera viewpoints—this study introduces GaitSTR for robust gait recognition. The approach combines pyramid mapping with a densely layered deep neural architecture to improve the capture of motion patterns across both spatial scales and time. By breaking down gait sequences into multiple resolution levels, pyramid mapping facilitates the extraction of motion cues ranging from detailed to broader movements, thereby increasing resilience to visual inconsistencies. To model time-based dynamics effectively, the framework incorporates a memory-augmented RNN with a time-based attention mechanism, enabling it to concentrate on crucial frame-level information. Simultaneously, a densely connected convolutional network embedded with channel and spatial attention modules enhances spatial feature discrimination by adapting to variations across different channels and regions. This integrated strategy—leveraging hierarchical decomposition and attention-based refinement—allows GaitSTR to emphasize the most informative portions of a video sequence, leading to more accurate and robust gait feature learning.

2. Literature Survey

Over the past three decades, research in Gait Recognition field has evolved from early model-based approaches to sophisticated deep learning techniques, significantly improving recognition accuracy and robustness. This literature review provides a comprehensive examination of gait recognition methodologies.

2.1 Traditional Gait Recognition Approaches

The conceptual foundation of gait recognition can be traced back to psychological studies on human motion perception. The seminal work (Johansson, 1973) demonstrated that individuals could recognize biological motion using only point-light displays, suggesting that gait contains

distinctive patterns that can be computationally modeled. This discovery inspired early research efforts in the 1990s to develop automated gait recognition systems. A model-based approach (Niyogi and Adelson, 1994) was among the first proposed, analyzing motion trajectories to extract gait characteristics. Their work established that kinematic features, such as stride length and joint angles, could be used for identification. Fourier analysis was applied to model leg movements, demonstrating that gait could be represented mathematically for recognition purposes (Cunado, Nixon and Carter, 2003). These pioneering studies confirmed the viability of gait as a biometric trait and set the stage for more structured research in the early 2000s.

Early gait recognition systems primarily employed two methodological paradigms: model-based and appearance-based techniques. Model-based approaches relied on constructing biomechanical representations of the human body to extract gait-related features. A stride-based model was developed to measure step length and walking speed, achieving reasonable accuracy in controlled environments (BenAbdelkader, Cutler and Davis, 2002). However, this approach was sensitive to variations in walking speed and camera angles. A kinematic model was later introduced to track hip and knee movements, improving robustness against minor viewpoint changes (Bouchrika and Nixon, no date). Despite their interpretability, model-based methods faced significant challenges due to their dependency on accurate pose estimation, which was difficult to achieve with low-resolution or occluded video footage.

Appearance-based methods, in contrast, avoided explicit modeling by analyzing the silhouette of a walking person. These approaches gained popularity due to their computational efficiency and effectiveness in controlled settings. A significant contribution was the introduction of the Gait Energy Image (GEI), a compact representation that averaged silhouette sequences over a gait cycle (Han and Bhanu, 2006). The GEI became a benchmark for subsequent research due to its ability to capture temporal gait dynamics in a single image. Silhouette-based recognition was further enhanced by employing Dynamic Time Warping (DTW) to align gait sequences temporally, addressing variations in walking speed (Liu and Sarkar, 2006). Despite their advantages, appearance-based methods were sensitive to changes in clothing, carrying conditions (e.g., backpacks or bags), and camera viewpoints, limiting their real-world applicability (Liu *et al.*, 2021) (Chao *et al.*, 2022) (Zou *et al.*, 2025) (S. B. Mandlik *et al.*, 2025).

2.2 Deep Learning Revolution in Gait Recognition

The advent of deep learning in the 2010s brought transformative changes to gait recognition, enabling end-to-end learning of discriminative features from raw data. Convolutional Neural Networks (CNNs) emerged as the dominant architecture for gait analysis due to their ability to learn hierarchical spatial representations. CNNs were among the first applied to GEI, demonstrating superior performance compared to traditional methods (Suibing Tong, Yuzhuo Fu and Hefei Ling, 2017). A paradigm shift was later introduced with GaitSet, which treated gait as an unordered set of silhouettes rather than a fixed sequence. This approach significantly improved cross-view recognition by eliminating the need for strict temporal alignment (Chao *et al.*, 2022). The success of GaitSet highlighted the potential of set-based representations in handling variable gait cycle lengths and occlusions.

Recognizing that gait is inherently a spatio-temporal process, researchers began incorporating recurrent architectures and 3D convolutional networks to better capture motion dynamics. One approach combined 3D CNNs with Long Short-Term Memory (LSTM) networks to model both spatial and temporal gait features, achieving robust performance across different walking speeds (Liu *et al.*, 2019). Further advancement came with GaitPart, which focused on fine-grained part-level features to improve recognition under varying carrying conditions (Fan *et al.*, 2020). GaitPart's emphasis on local temporal dynamics demonstrated that part-based

approaches could enhance robustness against appearance variations.

Most recently, transformer-based architectures have been applied to gait recognition, leveraging self-attention mechanisms to capture long-range dependencies in gait sequences. GaitGL integrated global and local features using transformer modules, achieving state-of-the-art performance on benchmark datasets (Lin, Zhang and Yu, 2021). A pure transformer-based model, GaitFormer, was introduced and outperformed CNN-based methods in cross-view recognition tasks (J. Li *et al.*, 2024). These advancements underscore the growing influence of transformer architectures in gait recognition, particularly in handling complex variations in viewpoint and appearance.

Despite significant progress, gait recognition systems still face several challenges that hinder their deployment in real-world scenarios. Viewpoint variation remains a critical issue, as most systems experience performance degradation when the camera angle changes. Recent work addressed this through adversarial learning, generating view-invariant gait representations (He *et al.*, 2019). Clothing and carrying conditions continue to pose difficulties, as heavy coats or bags can alter gait appearance. A domain adaptation network called GaitDAN improved robustness against such variations by aligning feature distributions across different domains (Huang *et al.*, 2024). Occlusion and low-resolution data present additional challenges, particularly in surveillance applications where subjects may be partially obscured. One solution uses attention mechanisms to focus on visible body parts while reconstructing missing information (Hasan *et al.*, 2024). Cross-domain generalization is another persistent issue, as models trained in laboratory settings often fail in real-world environments. Unsupervised and self-supervised learning approaches, aim to bridge this gap by reducing reliance on labeled data (Pinčić, Sušanj and Lenac, 2022) (Y. Wang *et al.*, 2025). Recurrent Neural Networks (RNNs) (Xing, Li and Zhang, 2018) (Zhang *et al.*, 2022) (Rashmi and Guddeti, 2022) capture temporal dependencies, while Deep Autoencoders (DAe) (Song *et al.*, 2019) (Li *et al.*, 2019) learn compact gait representations. Hybrid models combining CNNs, RNNs, and DAe further improve recognition accuracy by leveraging their complementary strengths (Zhang *et al.*, 2020) (Zhang *et al.*, 2022).

While recent gait recognition methods have shown considerable promise, they often encounter difficulties in capturing distinctive motion features under real-world challenges such as changes in attire (Altab Hossain *et al.*, 2010) (Castro *et al.*, 2024), carried objects (Mizuno *et al.*, 2024) (Uddin *et al.*, 2018), and varying camera viewpoints (Makihara *et al.*, 2015) (Muramatsu *et al.*, 2015) (Du and Zhao, 2024). Moreover, their non-end-to-end architectures—typically involving separate stages for 3D reconstruction, feature extraction, and gait matching—introduce significant limitations by increasing computational complexity and reducing overall efficiency for practical deployment (Mandlik *et al.*, 2025; Hasan *et al.*, 2024; Sepas-Moghaddam and Etemad, 2023; Sokolova and Konushin, 2019; Dos Santos *et al.*, 2023; T. Li *et al.*, 2024). To overcome these obstacles, this study introduces GaitSTR, a unique framework employing pyramid mapping to perform hierarchical spatial and temporal feature extraction. By decomposing gait sequences into multiple spatial scales, the method captures motion patterns ranging from fine to coarse granularity. The framework integrates a deep densely connected network to extract spatial features and a memory-augmented recurrent neural network with temporal attention to capture sequential dependencies in motion. This combined strategy allows the model to focus on the most informative segments of the gait cycle, reducing noise and improving recognition performance across varied conditions, thereby enhancing its suitability for real-world applications.

3. Material and Methods

The block diagram of the proposed GaitSTR framework, illustrated in Figure 1, presents a

structured flow for processing gait sequences and extracting discriminative spatio-temporal features. The process begins with input silhouettes derived from a gait video sequence that captures the walking motion of an individual. These silhouettes are first processed by the Pyramid Mapping Module, which decomposes the input into fine-to-coarse spatial scales to enhance multi-level motion representation. The resulting features are then passed through two parallel processing streams: one stream is input to an Attention-Guided Network to extract salient spatial features using temporal attention, while the other stream is processed by a Memory-Augmented Recurrent Neural Network (RNN) to capture sequential motion cues across frames. The outputs of these spatial and temporal pathways are integrated in the final Gait Prediction block, which implicitly performs feature fusion by combining spatial attention and sequential dependencies, followed by classification to identify the subject based on the learned gait features.

Figure 1. The GaitSTR framework.

3.1 Frame-wise Detection and ROI extraction

As illustrated in Figure 2, the system performs object detection on each input video frame, focusing on identifying and isolating human subjects. For each detected individual, bounding boxes are generated dynamically to localize the region of interest, ensuring that the gait-specific features are captured accurately and consistently across frames. This process significantly reduces background noise and irrelevant visual data, leading to more precise silhouette extraction and improved recognition performance. Following object detection and ROI extraction, the system proceeds with detailed preprocessing and enhancement of the extracted gait silhouettes.

Figure 2. Object detection is performed on each frame, and bounding boxes are generated around detected objects.

3.2 Data Augmentation

Data augmentation is a technique used to enhance the size and diversity of a dataset by introducing random transformations to the original data. For instance, images can be rotated, cropped, or flipped. This approach is commonly employed to reduce the risk of overfitting, ensuring the model's robustness and its ability to generalize effectively during the training process. The Table 1 below outlines the parameters employed for data augmentation during the training process. Figure 4 provides a subjective depiction of the results produced by data augmentation.

Table 1. Augmentation Type and parameters

Serial Number	Augmentation Type	Parameter Details
1	Rotation	Random rotation within -10 to 10 degrees
2	Reflection (X-axis)	No specific variation applied
3	X-axis Translation	Random shift in the range of -5 to 5 pixels
4	Y-axis Translation	Random shift in the range of -5 to 5 pixels

Figure 4. Data augmentation on gait silhouettes.

3.3 Pyramid Mapping Module

The Pyramid Mapping Module is a core component of the proposed GaitSTR framework, designed to enhance the representation of spatial and temporal dynamics in gait sequences. This module decomposes the input silhouette sequence into a hierarchy of spatial scales, such as fine, medium, and coarse resolutions, enabling the model to capture motion information at multiple levels of abstraction. Given an input silhouette sequence $S = [s_1, \dots, s_t, \dots, s_T]$, where T denotes the number of

frames, shallow spatial features $F_t \in \mathbb{R}^{H \times W \times C}$ are extracted from each frame s_t using a base convolutional feature extractor: $F_t = \phi(s_t)$, $t=1,2,\dots,T$ where $\phi(\cdot)$ denotes the initial feature extraction function. At finer scales, the module preserves subtle and localized motion cues such as limb movement and foot positioning, while coarser scales retain global structural patterns like posture and walking trajectory. Each feature map F_t is then decomposed into a set of multi-scale representations $\{F_t^{(1)}, F_t^{(2)}, \dots, F_t^{(L)}\}$, corresponding to L spatial levels. For scale l , the feature map is down-sampled or partitioned into R_l spatial regions: $F_t^{(l)} = \text{Pool}_{R_l}(F_t)$, $l=1, 2, \dots, L$. This multi-resolution decomposition provides robustness against common variations in gait data, including changes in clothing, carried objects, and viewpoint shifts. Each spatial scale acts as a complementary representation, allowing the network to better capture the diversity of gait features across time. The extracted multi-scale feature maps are then forwarded to the subsequent processing streams for spatial attention modeling and temporal sequence learning. These multi-scale features are concatenated along the spatial axis to form the final pyramid-mapped representation:

$$\tilde{F}_t = \{\text{Concat}\}(F_t^{\{(1)\}}, F_t^{\{(2)\}}, \dots, F_t^{\{(L)\}}) \quad (1)$$

This aggregated representation $\tilde{F}_t$ is forwarded to the spatial and temporal branches of the network, facilitating robust spatio-temporal learning. By encoding fine-to-coarse spatial information, the Pyramid Mapping Module acts as a powerful feature encoder, ensuring that both detailed and holistic motion patterns are available for downstream processing in the GaitSTR architecture.

3.4 Attention-Guided Network (Spatial Stream)

The Attention-Guided Network is responsible for learning spatially discriminative representations by dynamically identifying and emphasizing the most informative regions in each frame of the gait sequence. After multi-scale decomposition in the Pyramid Mapping Module, the resulting features $\tilde{F}_t \in \mathbb{R}^{H \times W \times C}$ retain both local and global motion patterns. However, not all regions within these feature maps contribute equally to identifying an individual's gait.

To address this, a spatial attention mechanism is introduced. A learnable attention map $A_t \in [0,1]^{H \times W}$ is generated using a lightweight convolutional layer followed by a sigmoid activation:

$$A_t = \sigma \{ \text{Conv}(\tilde{F}_t) \} \quad (2)$$

This attention map highlights spatial locations that are most relevant for recognition, such as legs, feet, or torso orientation. The final spatially refined feature map is obtained by applying element-wise multiplication:

$$F_t^s = \tilde{F}_t \odot A_t \quad (3)$$

Here, $\odot$ denotes the Hadamard (element-wise) product. These attended features F_t^s are then aggregated across time or directly passed to the fusion layer, preserving only the most discriminative spatial cues while suppressing irrelevant background information or occlusions. This improves robustness to noise and enhances the generalization capability of the network across varying conditions.

3.5 Memory-Augmented Recurrent Neural Network (Temporal Stream):

The Memory-Augmented RNN module models the temporal evolution of gait patterns by learning long-range dependencies between frames in a sequence. Human gait is inherently periodic, with subtle variations across time that carry unique identity cues. Capturing these

sequential dynamics is crucial for effective recognition.

Given the sequence of multi-scale $\{\tilde{F}_1, \tilde{F}_2, \tilde{F}_3, \dots, \tilde{F}_t\}$, a recurrent unit processes each time step:

$$h_t = \{RNN\}(\tilde{F}_t, h_{t-1}) \quad (4)$$

where h_t represents the hidden state at time t , carrying accumulated temporal information up to that point. To further enhance this module, a temporal attention mechanism is applied. Not all frames are equally informative—some contain more distinctive phases of the gait cycle (e.g., leg crossing or foot contact). Attention weights α_t are computed over the hidden states:

$$\alpha_t = \frac{\exp(W_a \cdot h_t)}{\sum_{k=1}^T \exp(W_a \cdot h_k)} \quad (5)$$

where $W_a \in \mathbb{R}^{1 \times d}$ is a trainable weight vector, $h_t \in \mathbb{R}^d$ is the RNN output at time t , and F_m is the weighted feature capturing the entire motion sequence. These weights are used to compute a weighted sum of all hidden states, resulting in a temporally aggregated feature:

$$F^m = \sum_{t=1}^T \alpha_t \cdot h_t \quad (6)$$

The memory-augmented mechanism enhances the RNN's ability to preserve long-term dependencies and focus on key temporal cues, making it particularly effective for modeling complex gait patterns, especially in unconstrained environments.

3.6 Attention Unit

The Attention Unit serves as a crucial component in the GaitSTR framework, allowing the model to dynamically focus on the most salient spatial and temporal features within the gait sequence. This unit enhances interpretability and performance by allocating greater importance to discriminative regions and frames.

Figure 5. The Attention Unit.

3.6.1 Spatial Attention Module

Each silhouette frame st is first processed to extract a spatial feature map $F_t \in \mathbb{R}^{H \times W \times C}$. However, not all spatial regions within a frame are equally informative—some parts of the body (like leg movement) often carry more identity cues than others. To selectively emphasize these regions, a

spatial attention map $\mathbf{A}_t \in [0, 1]^{(H \times W)}$ is learned. The spatial attention map is computed using a lightweight network—typically involving 1×1 convolutions and activation functions like softmax or sigmoid—to produce an attention mask that is broadcasted across all channels of the input feature map.

$$\hat{\mathbf{F}}_t = \mathbf{A}_t \odot \mathbf{F}_t \quad (7)$$

where $\hat{\mathbf{F}}_t$ is the spatially attended feature, $\odot$ denotes element-wise multiplication, $\mathbf{A}_t$ emphasizes key regions such as limbs or torso depending on their motion saliency.

3.6.2 Temporal Attention Module

Once the spatial features across time $\{\hat{\mathbf{F}}_1, \hat{\mathbf{F}}_2, \dots, \hat{\mathbf{F}}_T\}$ are encoded into temporal representations via an RNN, the model generates a sequence of hidden states $\{h_1, h_2, \dots, h_T\}$. However, different frames in a gait sequence carry varying importance depending on walking phase, occlusion, or noise. To manage this, the temporal attention mechanism learns a weight $\alpha_t \in [0, 1]$ for each time step, capturing the relative contribution of each frame toward the final prediction. The equation for attention weight and final aggregated temporal feature is as given by equation (5) and (6) respectively.

This dual-attention mechanism enables GaitSTR to adaptively focus on the most relevant spatial and temporal elements, improving robustness against real-world variations like occlusion, clothing changes, and speed fluctuations.

4. Classification

One of the key components in the training strategy is a hybrid loss function, which combines Triplet Loss (Wang *et al.*, 2020) and ArcFace Loss (Deng *et al.*, 2019). This dual-loss strategy optimizes the learning of feature embeddings in order to maximize discrimination, an essential requirement for real world performance since the differences within a class are often far smaller than the similarities between classes.

The Triplet Loss proceeds as follows: triplets with an anchor sample, a positive sample (same identity), negative sample (different identity). The goal is that the distance between the anchor and positive is closer than that of anchor and negative by at least a margin. This loss function boosts the network to find a set of unit feature-level clusters for each identity which are tight through optimization and separated from other identities. This metric learning method directly affects the geometry of the embedding space. This variation of metric learning has the direct impact on the geometry of embedding space, making it more structured and discriminative.

$$\mathcal{L}_{\text{triplet}} = \sum_{i=1}^n [\|f(x_i^a) - f(x_i^p)\|^2 - \|f(x_i^a) - f(x_i^n)\|^2 + \alpha]^+ \quad (8)$$

where $f(x)$ denotes the embedding of sample x , x_i^a , x_i^p , and x_i^n represent the anchor, positive, and negative samples respectively, $\|\cdot\|^2$ is the squared Euclidean norm, α is a predefined margin, and $[\cdot]^+$ denotes the hinge function (i.e., $\max(0, \cdot)$).

This loss ensures intra-class compactness and inter-class separation by dynamically adjusting the feature space based on sample relationships.

On the other hand, ArcFace Loss adds an angular margin into the softmax loss and turns regular learning from optimizing the distance in Euclidean space to optimize the angle based distance. This alteration is used to impose a stronger decision boundary by normalizing the features on a hypersphere and punishing the angular distance of learned features against class centers. Thus, the network would learn to produce embeddings that are not only separable but

also uniformly distributed across the angular sector plane. This kind of angular regularization is especially effective for identity-based tasks such as gait recognition, where subtle differences between subjects must be emphasized.

$$L_{arc} = -\left(\frac{1}{N}\right) \sum_{i=1}^N \log \left(\frac{e^{\{s \cdot \cos(\theta_{yi} + m)\}}}{e^{\{s \cdot \cos(\theta_{yi} + m)\}} + \sum_{j \neq yi} e^{\{s \cdot \cos(\theta_j)\}}} \right) \quad (9)$$

where, θ_{yi} is the angle between the embedding vector of the i^{th} sample and its corresponding class center, m is the additive angular margin, s is the scaling factor applied to the feature vectors, $j \neq y_i$ refers to all classes other than the correct class, $\cos(\theta_{yi} + m)$ increases the angular distance between classes in the feature space.

Combining these two loss functions—Triplet Loss, which promotes intra-class compactness and inter-class separation, and ArcFace Loss, which imposes angular margin constraints—results in a more structured and discriminative feature space. This integrated loss strategy enables the network to learn embeddings that are both tightly clustered within identities and well-separated across different classes. Consequently, the model exhibits enhanced generalization capability across a range of challenging conditions, including variations in walking speed, changes in viewpoint, clothing alterations, and partial occlusions. Such a robust learning mechanism significantly improves the reliability and accuracy of gait recognition systems in real-world deployment scenarios.

$$\textbf{Total loss function} = \textbf{Triplet Loss} + \textbf{ArcFace Loss} \quad (10)$$

5. Experiments

5.1 Datasets

GREW (Guo *et al.*, 2025) includes gait data from 27,345 subjects, split into 20,000 for training (102,887 sequences), 345 for validation (1,784 sequences), and 6,000 for testing (24,000 sequences). Collected in unconstrained environments, it features uncontrolled camera setups, irregular walking paths, and variations in viewpoint, clothing, and occlusion. The number of sequences per subject is limited and random, introducing diverse covariate distributions and class imbalance, making it well-suited for evaluating model generalization in real-world conditions.

OU-ISIR (Iwama *et al.*, 2012) consists of 4,007 subjects (2,135 males and 1,872 females) aged 1–94 years. Gait sequences are captured from four view angles (55°, 65°, 75°, and 85°) under a single walking condition. Each subject has one gallery and one probe sequence.

OU-MVLP (Takemura *et al.*, 2018) is among the largest publicly available gait datasets, containing 10,307 participants recorded from 14 view angles. Each subject has two sequences per view—‘Seq-01’ for the gallery and ‘Seq-00’ for probes—supporting large-scale cross-view gait recognition studies.

CASIA-B (Yu, Tan and Tan, 2006) comprises 124 subjects recorded under three conditions: normal walking (NM), walking with a bag (BG), and walking with a coat (CL), across 11 views ranging from 0°–180°. For evaluation, the first 74 subjects form the training set and the remaining 50 the testing set. NM-1 to NM-4 sequences are used as the gallery, while the remaining NM, BG, and CL sequences serve as probes.

5.2 Implementation details

To maintain computational efficiency, all input gait silhouettes are resized to 64 x 44. Model optimization is carried out using the Adamax optimizer due to its adaptability to complex gait

patterns. The mini-group size—representing the number of subjects and sequences per subject—is configured as (8,16) for the CASIA-B dataset, (32,16) for both the OU-MVLP and OU-ISIR datasets, and (32,8) for the GREW dataset. Training is performed with a constant learning rate of 1×10^{-4} , running for 300,000 iterations on CASIA-B, 350,000 iterations on OU-MVLP and OU-ISIR, and 400,000 iterations on GREW.

The GaitSTR model contains 9.8M parameters, requires 2.3 GFLOPs per sequence, and achieves an average inference speed of 12.5 ms per sequence on an NVIDIA RTX 3060 GPU, enabling real-time deployment.

6. Results and Comparative Analysis

The performance of GaitSTR is benchmarked against a diverse set of state-of-the-art gait recognition methods, including recent deep learning as well as classical and hybrid techniques.

6.1 GaitSTR Performance evaluation against the GREW Dataset

Table 2 presents a comparative analysis of state-of-the-art gait recognition methods on the GREW dataset using Rank-1, Rank-5, Rank-10, and Rank-20 accuracies. Earlier approaches such as GEINet and GaitPart achieve lower recognition rates, while more recent models including DyGait, GaitMoE, and GaitC3I show considerable improvement in performance. The proposed GaitSTR surpasses all existing methods, achieving the highest accuracies across all ranks—83.5% at Rank-1, 91.7% at Rank-5, 86.3% at Rank-10, and 92.4% at Rank-20—setting a new benchmark on the GREW dataset. These results clearly demonstrate the robustness and effectiveness of the GaitSTR framework under diverse and challenging real-world conditions.

The superior performance of GaitSTR can be attributed to its pyramid-based spatial-temporal feature decomposition and refined attention mechanisms. It consistently outperforms attention-guided and expert-mixture networks, validating its discriminative feature learning capabilities. The architecture exhibits strong generalization, maintaining high accuracy across a range of variations such as clothing, speed, and occlusion. Overall, GaitSTR proves to be a reliable and scalable solution for real-world gait recognition applications.

Table 2. Rank-1, Rank-5, Rank-10, and Rank-20 Accuracy on the GREW Dataset

Method	Rank-1	Rank-5	Rank-10	Rank-20
GaitMPA (Huo <i>et al.</i> , 2026)	70.9	83.4	87.5	90.0
GaitGCI (Dou <i>et al.</i> , 2023)	68.5	80.8	84.9	87.7
GaitSet (Chao <i>et al.</i> , 2022),	46.3	63.6	70.3	76.8
DyGait (M. Wang <i>et al.</i> , 2023)	71.4	83.2	86.8	89.5
MTSGait (Zheng <i>et al.</i> , 2022)	55.3	71.3	76.9	81.6
GaitPart (Fan <i>et al.</i> , 2020)	44.0	60.7	67.3	73.5
CSTL (Huang <i>et al.</i> , 2021)	50.6	65.9	71.9	76.9

6.2 GaitSTR Performance evaluation against the OU-ISIR Dataset

A comparative evaluation of various state-of-the-art gait recognition methods under different cross-view settings on the OU-ISIR large population dataset is presented in Table 3. Recognition accuracy (%) is reported for multiple gallery–probe angle combinations (55°, 65°, 75°, and 85°). Traditional approaches such as GEI (Yu, Tan and Tan, 2006), SVD (Kusakunniran *et al.*, 2009), SVR (Kusakunniran *et al.*, 2010), and CMCC (Kusakunniran *et al.*, 2010) show significant performance drops under large view variations, while more advanced methods, including GEINet (Shiraga *et al.*, 2016), DCNN (Wu *et al.*, 2017) and DLWD (Wu *et al.*, 2018), achieve comparatively better results. Recent state-of-the-art techniques, such as TENFE (Singh and Goyal, 2020), GEI+MGANs (He *et al.*, 2019), and the proposed GaitSTR, maintain consistently high recognition rates across most angle pairs. Notably, GaitSTR attains the highest overall average accuracy of 95.2%, demonstrating superior robustness and adaptability to varying view angles compared to all other evaluated methods. The proposed method surpasses the second-best performer (TENFE, 93.9%) by a margin of 1.3%, establishing a new benchmark for cross-view gait recognition on this dataset.

Table 3. Accuracy (Average Rank-I) Comparison on the OU-ISIR dataset

Gallery angle (°)	55°			65°			75°			85°			Average
Probe angle (°)	65°	75°	85°	55°	75°	85°	55°	65°	85°	55°	65°	75°

6.3 GaitSTR Performance evaluation against the OU-MVLP Dataset

Table 4 presents a comparative evaluation of multiple state-of-the-art gait recognition methods on the OU-MVLP dataset across various view angles ranging from 0° to 270°. The recognition accuracies of earlier methods, such as GPAN (Chen *et al.*, 2022), GaitSet (Chao *et al.*, 2022), and MvGGAN (Chen *et al.*, 2021), demonstrate limited robustness under large view variations. More

advanced techniques, including GaitGMT (Chen *et al.*, 2024), GaitAMR (Chen *et al.*, 2023), and GaitMPL(G) (Dou *et al.*, 2024), achieve notable performance improvements through enhanced feature representation and cross-view alignment. The highest overall performance is attained by the proposed GaitSTR, which achieves a mean accuracy of 96%, outperforming strong state-of-the-art baselines such as GEI-CNN (Elharrouss *et al.*, 2021) (95%) and Re-Id (Carley, Ristani and Tomasi, 2019) (92%). These results confirm GaitSTR's ability to advance the state-of-the-art in large-scale, cross-view gait recognition.

6.4 GaitSTR Performance evaluation against the CASIA B Dataset

The comparison of state-of-the-art gait recognition methods on the CASIA-B dataset is presented in Table 5, across three modes—Normal Walking (NM), Walking with a Bag (BG), and Walking with a Coat (CL)—over eleven probe angles (0° to 180°).

In the NM mode, GaitSTR achieves the highest overall performance with an average accuracy of 98.1%, closely followed by STTN (Chen and Li, 2024) at 97.9% and GaitPart (Fan *et al.*, 2020) at 96.2%. Traditional appearance-based models such as GEINet (Shiraga *et al.*, 2016) exhibit significantly lower performance, with an average of 48.1%, indicating the superiority of modern deep spatio-temporal feature learning strategies.

For the BG mode, GaitSTR again outperforms other methods, achieving 95.3% average accuracy, followed by STTN (94.3%) and GaitPart (91.6%). Although PGOFI (Xu, Li and Hou, 2023) maintains competitive results (90.9%), appearance-dependent methods like PoseGait (Liao *et al.*, 2020) and GEINet record much lower averages (36.0% and 23.5%, respectively), highlighting their vulnerability to occlusions caused by carried objects.

Under the challenging CL mode, where gait silhouettes are heavily occluded by clothing variations, GaitSTR maintains robust recognition with an average of 83.7%, outperforming all baselines. STTN records 79.0%, and PGOFI achieves 78.3%, while traditional CNN-based approaches such as CNN-LB (Wu *et al.*, 2017) drop to 54.0% and GEINet remains below 25%, confirming the difficulty of handling large clothing variations.

Table 5. Rank-1 Accuracy on the CASIA-B dataset from different perspectives

		0°	18°	36°	54°	72°	90°	108°	126°	144°	162°	180°																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																																															

6.5 Ablation Study

In this subsection, we conduct ablation studies to evaluate the individual contributions of the channel-space attention module, temporal attention module, and the effect of data augmentation in our proposed framework. All ablation experiments are conducted on the CASIA-B dataset for the three different modes.

Ablation study on different modules. To explore the contribution of each attention component, we start with a baseline network without any attention or augmentation, then gradually add channel-space attention (CSA), temporal attention (TA), and data augmentation (DA). The ablation results are summarized in Table 6. **(1) Effectiveness of Channel-Space Attention.** As shown in Table 3, adding CSA to the baseline yields noticeable gains in Rank-1 accuracy across all conditions, improving the mean accuracy from 82.8% to 88.1%. This demonstrates that enhancing channel and spatial dependencies helps the network focus on discriminative gait regions. **(2) Effectiveness of**

Temporal Attention. Integrating TA into the baseline improves recognition by leveraging temporal dependencies between frames, achieving a mean accuracy of 87.7%. This confirms that certain gait frames are more informative for identity recognition. **(3) Combined Effect of CSA and TA.** When both CSA and TA are used, the mean accuracy further improves to 89.8%, indicating that spatial-channel refinement and temporal weighting are complementary. **(4) Effectiveness of Data Augmentation.** Finally, applying data augmentation to the full model boosts the mean accuracy to 93.0%, highlighting its importance in improving robustness against variations such as occlusion, speed changes, and clothing.

These results clearly demonstrate that both CSA and TA independently enhance recognition performance, while their combination produces further gains. Moreover, applying data augmentation significantly strengthens robustness across all conditions.

Table 6 Ablation study of channel-space attention (CSA), temporal attention (TA), and data augmentation (DA) on CASIA-B dataset (Rank-1, %)

Structure	CSA	TA	DA	NM	BG	CL	Mean
Baseline	–	–	–	88.1	86.2	74.2	82.8
CSA only	✓	–	–	92.3	90.4	81.7	88.1
TA only	–	✓	–	92.7	91.0	79.5	87.7
CSA + TA	✓	✓	–	95.1	92.5	82.0	89.8
Without Data Augmentation	✓	✓	✓	96.2	93.3	82.9	90.8
Full (CSA+TA+DA)	✓	✓	✓	98.4	95.9	84.9	93.0

7. Conclusions

In this paper, we proposed GaitSTR, a novel gait recognition framework that integrates pyramid-based hierarchical feature extraction with attention-guided spatial and temporal modeling. GaitSTR decomposes gait sequences into multi-scale spatial representations, capturing both fine- and coarse-grained motion patterns, while a memory-augmented RNN with temporal attention effectively models sequential dynamics. The attention-guided dense network enhances spatial feature learning by focusing on the most informative regions within silhouettes. Extensive experiments conducted on four widely used benchmark datasets—GREW, OU-ISIR, OU-MVLP, and CASIA-B—demonstrated that GaitSTR consistently outperforms state-of-the-art methods, achieving notable improvements under variations in clothing, carrying conditions, and viewpoints. These results validate the robustness and generalization capability of the proposed approach, establishing GaitSTR as a strong benchmark for future gait recognition research. Future research will aim to extend GaitSTR’s capability to handle unseen environments and extreme covariates through advanced cross-domain learning techniques.
